Abstract. We consider some questions about formal languages that arise when inverses of letters, words and languages are defined. The reduced representation of a language over the free monoid is its unique equivalent representation in the free group. We show that the class of regular languages is closed under taking the reduced representation, while the class of context-free languages is not. We also give an upper bound on the state complexity of the reduced representation of a regular language, and prove upper and lower bounds on the length of the shortest reducible string in a regular language. Finally we show that the set of all words which are equivalent to the words in a regular language can be nonregular, and that regular languages are not closed under taking a generalized form of the reduced representation.

1 Introduction

A word in a free group can be represented in many different ways. For example, aaa^{-1} and $aa^{-1}baa^{-1}b^{-1}a$ are two different ways to write the word a . Among all the different representations, however, there is one containing no occurrences of a letter next to its own inverse. We call such a word *reduced*. In this paper we consider some basic questions about formal languages and their reduced representations. In previous work on automatic groups, these notions of inverse symbols and reduced words have been studied, but only with regards to automata that are assumed to generate groups [1].

First we define some standard notation. A deterministic finite automaton (DFA) is denoted by a quintuple $(Q, \Sigma, \delta, q_0, F)$ where Q is the finite set of states, Σ is the finite input alphabet, $\delta : Q \times \Sigma \rightarrow Q$ is the transition function, $q_0 \in Q$ is the initial state, and $F \subseteq Q$ is the set of accepting states. We generalize δ to the usual extended transition function with domain $Q \times \Sigma^*$. We use similar notations to represent a nondeterministic finite automaton with ϵ -transitions (ϵ -NFA), except the transition function is $\delta : Q \times (\Sigma \cup \{\epsilon\}) \rightarrow 2^Q$. In an ϵ -NFA it

is possible to have ϵ -transitions, which are transitions that can be taken without reading input symbols. For a DFA or ϵ -NFA M , $L(M)$ is the language accepted by M . For any $x \in \Sigma^*$, $|x|$ denotes the length of x , and $|x|_a$ for some $a \in \Sigma$ denotes the number of occurrences of a in x . We let $|\Sigma|$ denote the alphabet size. We use the terms *prefix* and *factor* in the following way. If there exist $x, z \in \Sigma^*$ and $w = xyz$, we say that y is a factor of w . If $x = \epsilon$, we also say that y is a prefix of w . If y is a factor or prefix of w and $y \neq w$, then y is a *proper* factor or a proper prefix of w , respectively.

In addition to this standard notation, we also define some notation specific to our problem. For a letter a , we denote its inverse by a^{-1} , and we let the empty word, ϵ , be the identity. We consider only alphabets of the form $\Sigma = \Gamma \cup \Gamma^{-1}$, where $\Gamma = \{1, 2, \dots\}$ and $\Gamma^{-1} = \{1^{-1}, 2^{-1}, \dots\}$. For a word $w \in \Sigma^* = a_1 a_2 \dots a_n$, we denote its inverse by $w^{-1} = a_n^{-1} \dots a_2^{-1} a_1^{-1}$, and for a language $L \subseteq \Sigma^*$, we let $L^{-1} = \{w^{-1} : w \in L\}$. Note that taking the inverse of a word is equivalent to reversing it and then applying a homomorphism that maps each letter to its inverse. Now, we introduce a reduction operation on words, consisting of removing factors of the form aa^{-1} , with $a \in \Sigma$. More formally, let us define the relation $\vdash \subseteq \Sigma^* \times \Sigma^*$ such that, for all $w, w' \in \Sigma^*$, $w \vdash w'$ if and only if there exists $x, y \in \Sigma^*$ and $a \in \Sigma$ satisfying $w = xaa^{-1}y$ and $w' = xy$. As usual, $\vdash^*$ denotes the reflexive and transitive closure of $\vdash$.

Lemma 1. *For each $w \in \Sigma^*$ there exists exactly one word $r(w) \in \Sigma^*$ such that $w \vdash^* r(w)$ and $r(w)$ does not contain any factor of the form aa^{-1} , with $a \in \Sigma$.*

Proof. First, we prove that if $w \vdash w'$ and $w \vdash w''$ then there exists $u \in \Sigma^*$ such that $w' \vdash^* u$ and $w'' \vdash^* u$, i.e., in the terminology of rewriting systems, Σ^* with the relation $\vdash$ is a local confluent system.

To this aim, suppose that $w = x'aa^{-1}y' = x''bb^{-1}y''$, $w' = x'y'$, $w'' = x''y''$, for some $x', x'', y', y'' \in \Sigma^*$, $a, b \in \Sigma$, and, without loss of generality, that $|x'| \leq |x''|$. If $|x'| = |x''|$ then $w' = w''$, hence, we can take $u = w'$. Otherwise, if $|x'aa^{-1}| \leq |x''|$ then $w = x'aa^{-1}zbb^{-1}y''$, for some $z \in \Sigma^*$ and the desired word is $u = x'zy''$. In the only remaining case, $x'a = x''$, which implies that $b = a^{-1}$ and $w = x'aa^{-1}ay''$. Hence $w' = w'' = x'ay''$, so we just take $u = w'$.

Since $w \vdash w'$ implies that $|w'| = |w| - 2$, no infinite reduction sequences are possible. By Newman's lemma [5], this implies that the system is confluent, namely, for each $w \in \Sigma^*$ there exists exactly one word $r(w)$ such that $w \vdash^* r(w)$ and, for each $x \in \Sigma^*$, $r(w) \vdash^* x$ implies $x = r(w)$, i.e., $r(w)$ does not contain any factor aa^{-1} . $\square$

We define the *reduced representation* of a word $w \in \Sigma^*$ as the word $r(w)$ given in Lemma 1, i.e., the word which is obtained from w by repeatedly replacing with ϵ all factors of the form aa^{-1} , for any letter $a \in \Sigma$, until no such factor exists. If $r(w) = \epsilon$ we say that w is *reducible*. We can extend this to languages so that for $L \subseteq \Sigma^*$, we let $r(L) = \{r(w) : w \in L\}$.

Given a language L , the $\vdash$ -closure of L is the set of the words which can be obtained by “reducing” words of L , i.e., the set $\{x \in \Sigma^* : \exists w \in L \text{ s.t. } w \vdash^* x\}$. Notice that $r(L)$ coincides with the intersection of the $\vdash$ -closure of L and $r(\Sigma^*)$.

Section 2 examines the reduced representations of regular and context-free languages. Section 3 provides some bounds on the state complexity of reduced representations. In Section 4 we look at bounds on the length of the shortest word in a regular language that reduces to ϵ . Section 5 demonstrates counterexamples for some other natural questions.

2 Closure of Reduced Representation

When considering the reduced representations of languages, it is natural to wonder if common classes of languages are closed under this operation. In this section we show that if a language L is regular then $r(L)$ is regular, but if L is context-free then $r(L)$ does not need to be context-free.

Lemma 2. *For $\Sigma = \Gamma \cup \Gamma^{-1}$, where $\Gamma = \{1, \dots, k\}$ and $\Gamma^{-1} = \{1^{-1}, \dots, k^{-1}\}$, there exists a DFA M_k of $2k + 2$ states that accepts $r(\Sigma^*)$.*

Proof. We notice that a word w is reduced if and only if it does not contain the factor aa^{-1} , for each $a \in \Sigma$. This condition can be verified by defining an automaton M_k that remembers in its finite control the last input letter. To this aim, the automaton has a state q_a for each $a \in \Sigma$. If in the state q_a the symbol a^{-1} is received, then the automaton reaches a dead state q_{-1} .

Formally, M_k is the DFA $(Q, \Sigma, \delta, q_0, F)$ defined as follows (see Figure 1 for an example): $Q = \{q_0, q_{-1}\} \cup \{q_i : i \in \Gamma \cup \Gamma^{-1}\}$, $F = Q \setminus \{q_{-1}\}$, and

$$\delta(q_a, c) = \begin{cases} q_c, & \text{if } a \neq c^{-1} \text{ and } q_a \neq q_{-1}; \\ q_{-1}, & \text{otherwise.} \end{cases}$$

□

Lemma 3. *Given an ϵ -NFA $M = (Q, \Sigma, \delta, q_0, F)$ with n states, an automaton M' accepting the $\vdash$ -closure of $L(M)$ can be built in time $O(n^4)$.*

Proof. The idea behind the proof is to present an algorithm that given M computes M' by adding to M ϵ -transitions corresponding to paths on reducible words. The algorithm is similar to a well known algorithm for minimizing DFAs [3, p. 70]. It uses a directed graph $G = (Q, E)$ to remember ϵ -transitions. For each pair of states s, t , the algorithm also keep a set $l(s, t)$ of pairs of states, with the following meaning: if $(p, q) \in l(s, t)$ and the algorithm discovers that there is a path from s to t on a reducible word (and hence it adds the edge (s, t) to G), then there exists a path from p to q on a reducible word (thus, the algorithm can also add the edge (p, q)).

```

 $E \leftarrow$  transitive closure of  $\{(p, q) \mid q \in \delta(p, \epsilon)\}$ 
for  $s, t \in Q$  do  $l(s, t) \leftarrow \emptyset$ 
for  $p, q, s, t \in Q$  do
  if  $\exists a \in \Sigma$  s.t.  $s \in \delta(p, a)$  and  $q \in \delta(t, a^{-1})$  then
    if  $(s, t) \in E$  then  $E \leftarrow \text{update}(E, (p, q))$ 
    else  $l(s, t) \leftarrow l(s, t) \cup \{(p, q)\}$ 

```

Fig. 1. M_2 , a DFA that accepts $r(\Sigma^*)$ for $|\Sigma| = 4$.

The subroutine *update* returns the smallest set E' having the following properties:

- $E \cup \{(p, q)\} \subseteq E'$;
- if $(p', q') \in E'$ then each element belonging to $l(p', q')$ is in E' ;
- the graph (Q, E') is transitive.

At the end of the execution, the automaton M' is obtained by adding to M an ϵ -transition from a state p to a state q for each edge (p, q) in the resulting graph G .

Now, we show that the language accepted by M' is the $\vdash$ -closure of $L(M)$. To this aim, we observe that for all $p, q, s, t \in Q$, such that $s \in \delta(p, a)$ and $q \in \delta(t, a^{-1})$ are transitions of M for some $a \in \Sigma$, if M' contains an ϵ -transition from s to t then it must contain also an ϵ -transition from p to q . In fact, when the algorithm examines these 4 states in the loop, if (s, t) is in E then the algorithm calls *update* to add (p, q) to E . Otherwise, the algorithm adds (p, q) to $l(s, t)$. Since M' finally contains the ϵ -transition from s to t , then there is a step of the algorithm, after the insertion of (p, q) in $l(s, t)$, adding the pair (s, t) to E . The only part of the algorithm able to perform this operation is the subroutine *update*.¹ But when the subroutine adds the pair (s, t) to E then it must add all the pairs in $l(s, t)$. Hence, M' must also contain an ϵ -transition from p to q . As

¹ Notice that the pair (s, t) can be added to E by the subroutine *update* either because it is the second argument in the call of the subroutine, or because it belongs to a list $l(p', q')$, where (p', q') is added to E in the same call, or because there is a path

a consequence, if $w \in L(M')$ and $w \vdash w'$ then $w' \in L(M')$, i.e., $L(M')$ is closed under $\vdash$. Since the algorithm does not remove the original transitions from M , $L(M) \subseteq L(M')$ and, hence, the $\vdash$ -closure of $L(M)$ is included in $L(M')$.

On the other hand, it can be easily shown that for each ϵ -transition of M' from a state p to a state q there exists a reducible word z such that $q \in \delta(p, z)$ in M . Using this argument, from each word $w \in L(M')$ we can find a word $x \in L(M)$ such that $x \vdash^* w$. This permit us to conclude that $L(M')$ accepts the $\vdash$ -closure of $L(M)$.

Now we show that the algorithm works in $O(n^4)$ time. A naive analysis gives a running time growing at least as n^4 . In fact, the second for-loop iterates over all state 4-tuples. Inside the loop the most expensive step is the subroutine *update*. This subroutine starts by adding an edge (p, q) to E . For each new edge (p', q') added to E the subroutine has to add all the edges in $l(p', q')$, while keeping the graph transitive. This seems to be an expensive part of the computation. However, we can observe that each set $l(p', q')$ contains less than n^2 elements. Furthermore, a set $l(p', q')$ is examined only once during the execution of the algorithm, namely when (p', q') is added to E . Hence, the total time spent while examining the sets l in all the calls of the subroutine *update* is $O(n^4)$. Furthermore, no more than n^2 edges can be inserted into G , and each insertion can be done in $O(n)$ amortized time while maintaining the transitive closure [4,6]. Summing up, we get that the overall time of the algorithm is $O(n^4)$. $\square$

By combining the results in the previous lemmata, we are now able to show the following:

Proposition 1. *Given an ϵ -NFA $M = (Q, \Sigma, \delta, q_0, F)$ with n states, an ϵ -NFA M_r such that $L(M_r) = r(L(M))$ can be built in $O(n^4)$ time.*

Proof. The language $r(L(M))$ is the intersection of the $\vdash$ -closure of $L(M)$ and $r(\Sigma^*)$. According to Lemma 3, from M we build an automaton M' accepting the $\vdash$ -closure of $L(M)$. Hence, using standard constructions, from M' and the automaton obtained in Lemma 2 (whose size is fixed, if the input alphabet is fixed), we get the automaton M_r accepting $r(M) = L(M') \cap r(\Sigma^*)$.

The most expensive part is the construction of M' , which uses $O(n^4)$ time. $\square$

Corollary 1. *For any $L \subseteq \Sigma^*$, if L is regular then $r(L)$ is regular.*

Now we turn our attention to context-free languages and prove that the analogue of Corollary 1 does not hold. For this we use the notion of a quotient of two languages.

Definition 1. *Given $L_1, L_2 \subseteq \Sigma^*$, the quotient of L_1 by L_2 is*

$$L_1/L_2 = \{w : \exists x \in L_2 \text{ such that } wx \in L_1\}$$

from s to t consisting of some arcs already in E and at least one arc added during the same call of *update*.

While the class of regular languages is closed under quotients, the class of context-free languages is not closed under this operation [2]. It turns out that the reduced representation of a language can be used to compute quotients.

Lemma 4. *For any two languages $L_1, L_2 \subseteq \Gamma^*$, the language $L_3 = r(L_1 L_2^{-1}) \cap \Gamma^*$ equals the quotient L_1/L_2 .*

Proof. We notice that $r(wxx^{-1}) = w$, for each $w, x \in \Gamma^*$. Hence, given $w \in \Gamma^*$, it holds that $w \in L_3 = r(L_1 L_2^{-1}) \cap \Gamma^*$ if and only if there exists $x \in L_2$ such that $wx \in L_1$. Therefore $L_3 = L_1/L_2$. $\square$

Corollary 2. *The class of context-free languages is not closed under $r()$.*

Proof. By contradiction, suppose that the class of context-free languages is closed under $r()$. Since this class is closed under the operations of reversal, morphism, concatenation and intersection with a regular language, for any two context-free languages L_1 and L_2 over Γ , the language $L_3 = r(L_1 L_2^{-1}) \cap \Gamma^*$ is also context-free. However, from Lemma 4, $L_3 = L_1/L_2$, implying that the class of context-free languages would be closed under quotient, a contradiction. $\square$

3 State Complexity of Reduced Representation

Here we look at some bounds on the state complexity of the reduced representation of a regular language.

Proposition 2. *For any ϵ -NFA, $M = (Q, \Gamma \cup \Gamma^{-1}, \delta, q_0, F)$ with n states, $\Gamma = \{1, 2, \dots, k\}$ and $\Gamma^{-1} = \{1^{-1}, 2^{-1}, \dots, k^{-1}\}$ for some positive integer k , there exists a DFA of at most $2^n(2k + 2)$ states that accepts $r(L(M))$.*

Proof. The upper bound follows from the algorithm used to prove Proposition 1. The first part of the construction (i.e., the construction of the automaton M' accepting the $\vdash$ -closure of the language accepted by M) does not increase the number of states. The resulting automaton M' can be converted into a DFA with 2^n states. Finally, to get an automaton accepting $r(L(M))$ we apply the usual cross-product construction to this automaton and to the DFA with $2k + 2$ states accepting $r(\Sigma^*)$ obtained in Lemma 2. The intersection results in a DFA of no more than $2^n(2k + 2)$ states. $\square$

Since each DFA is *a fortiori* an ϵ -NFA, the previous proposition gives an upper bound for the state complexity of the reduced representation.

4 Length of Shortest String Reducing to the Empty Word

Another interesting question is: given a DFA M of n states such that $\epsilon \in r(L(M))$, what is the shortest $w \in L(M)$ such that $r(w) = \epsilon$? We provide upper and lower bounds, and we examine the special case of small alphabets. First we provide an upper bound.

Proposition 3. *For any NFA $M = (Q, \Sigma, \delta, q_0, F)$ with n states such that there exists $w \in L(M)$ with $r(w) = \epsilon$, there exists $w' \in L(M)$ such that $|w'| \leq 2^{n^2-n}$ and $r(w') = \epsilon$.*

Proof. Suppose M accepts $w \in \Sigma^+$ such that $r(w) = \epsilon$. Then w can be decomposed in at least one of two ways. Either there exist $u, v \in \Sigma^+$ such that $w = uv$, $r(u) = \epsilon$ and $r(v) = \epsilon$ (Case 1), or there exist $u \in \Sigma^*$, $a \in \Sigma$ such that $w = au a^{-1}$ and $r(u) = \epsilon$ (Case 2). Any factor w' of w such that $r(w') = \epsilon$ can also be decomposed in at least one of these two ways, so we can recursively decompose w and the resulting factors until we have decomposed w into single symbols. So, we can specify a certain type of parse tree such that M accepts $w \in \Sigma^*$ with $r(w) = \epsilon$ if and only if we can build this type of parse tree for w .

Define our parse tree for a given w as follows. Every internal node corresponds to a factor w' of w such that $r(w') = \epsilon$, and the root of the whole tree corresponds to w . The leaves store individual symbols. When read from left to right, the symbols in the leaves of any subtree form the word that corresponds to the root of the subtree. Each internal node is of one of two types:

1. The node has two children, both of which are internal nodes that serve as roots of subtrees (corresponds to Case 1).
2. The node has three children, where the left and the right children are single symbols that are inverses of each other, and the child in the middle is empty or it is an internal node that is the root of another subtree (corresponds to Case 2).

An example is shown in Figure 2. Now, we fix an accepting computation of M on input w . We label each internal node t with a pair of states $p, q \in Q$ such that if w' is the factor of w that corresponds to the subtree rooted at t , and $w = xw'y$, then $p \in \delta(q_0, x)$ and $q \in \delta(p, w')$ are the states reached after reading the input prefixes x and xw' , respectively, during the accepting computation under consideration. (This also implies that $q_f \in \delta(q, y)$, with $q_f \in F$, and (q_0, q_f) is the label associated with the root of the tree.)

Fig. 2. An example parse tree for the word $w = a^{-1}bb^{-1}aa^{-1}b^{-1}b^{-1}bba$, without the state pair labels.

If the parse tree of w has two nodes t and u with the same state-pair label such that u is a descendent of t , then there exists a word shorter than w which is accepted and reduces to the empty word. This is because we can replace the subtree rooted at t with the subtree rooted at u . Furthermore, if an internal node t is labeled with a pair (q, q) , for some $q \in Q$, then the factor w' corresponding to the subtree rooted at t can be removed from w , obtaining a shorter reducible word. Hence, by a pigeonhole argument, we conclude that the height of the subtree corresponding to the shortest reducible word w is at most $n^2 - n$. We now observe that the number of leaves of a parse tree of height k defined according to our rules is at most 2^k . (Such a tree is given by the complete binary tree of height k , which has no nodes with three children. The avoidance of nodes with three children is important because such nodes fail to maximize the number of internal nodes in the tree, which in turn results in less than the maximum number of leaves.) This permits us to conclude that $|w| \leq 2^{n^2 - n}$. $\square$

Now we show that there is a lower bound that is exponential in the alphabet size and in the number of the states.

Proposition 4. *For all integers $n \geq 3$ there exists a DFA, M_n , with $n + 1$ states over the alphabet $\Sigma = \Gamma \cup \Gamma^{-1}$, where $\Gamma = \{1, 2, \dots, n - 2\}$ and $\Gamma^{-1} = \{1^{-1}, 2^{-1}, \dots, (n - 2)^{-1}\}$, with the property that if $w \in L(M_n)$ and $r(w) = \epsilon$, then $|w| \geq 2^{n-1}$.*

Proof. The proof is constructive. Let M_n be the DFA $(Q, \Sigma, \delta, q_0, F)$, illustrated in Figure 3, where $Q = \{q_{-1}, q_0, q_1, \dots, q_{n-1}\}$, $F = \{q_1\}$, and

$$\delta(q_a, c) = \begin{cases} q_1, & \text{if } c = 1 \text{ and } a = 0; \\ q_{a+1}, & \text{if } c = a^{-1} \text{ and } 1 \leq a \leq n - 2; \\ q_0, & \text{if either } c = a \text{ and } 1 \leq a \leq n - 2, \\ & \text{or } c = 1^{-1} \text{ and } a = n - 1. \end{cases}$$

Any other transitions lead to the dead state q_{-1} .

Fig. 3. M_n : an $n + 1$ state DFA with the property that for all $w \in L(M_n)$ such that $r(w) = \epsilon$, $|w| \geq 2^{n-1}$. The dead state is not shown.

Now we show that M_n has the desired property. Assume there exists $w \in L(M_n)$ such that $r(w) = \epsilon$. Then $|w|_a = |w|_{a^{-1}}$ for all $a \in \Sigma$. Since all words in $L(M_n)$ must contain the symbol 1 (due to the single incoming transition to the only accepting state), it follows that w must also contain 1^{-1} . Furthermore, the only possible transition from q_1 not leading to the dead state uses the symbol 1^{-1} . Hence w must begin with the prefix 11^{-1} . Since $\delta(q_0, 11^{-1}) = q_2$ and the only two transitions that leave q_2 are on 2 and 2^{-1} , w must contain both of 2 and 2^{-1} . Now assume that w contains the symbol i^{-1} with $1 < i < n - 2$. Then the state q_{i+1} must be reached while reading w , thus implying that the symbols $(i + 1)$ and $(i + 1)^{-1}$ also appear in w . Therefore, by induction, w must contain at least one occurrence of each $a \in \Sigma$.

Now we claim that w must contain at least 2^{n-2-a} occurrences of the symbol a , for $1 \leq a \leq n - 2$, and hence at least 2^{n-2-a} occurrences of the symbol a^{-1} .

We prove the claim by induction on $n - 2 - a$. The basis, $a = n - 2$, follows from the previous argument. Now, suppose the claim true for $k = n - 2 - a$. We prove it for $k + 1 = n - 2 - (a - 1)$. By the induction hypothesis, w contains at least 2^k occurrences of the symbol a and at least 2^k occurrences of a^{-1} . Observing the structure of the automaton, we conclude that to have such a number of occurrences of the two letters a and a^{-1} , the state q_k must be visited at least

2^{k+1} times. On the other hand, the only transition entering q_k is from the state q_{k-1} on the letter $(a-1)^{-1}$. Hence, w must contain at least $2^{k+1} = 2^{n-2-(a-1)}$ occurrences of $(a-1)^{-1}$ and, according to the initial discussion, at least $2^{k+1} = 2^{n-2-(a-1)}$ occurrences of $a-1$. This proves the claim.

By computing the sum over all alphabet symbols, we get that $|w| \geq 2(2^{n-2} - 1)$. However, since the symbol $(n-2)^{-1}$ must always be followed by the symbol 1^{-1} , w must actually contain one additional occurrence of each of 1 and 1^{-1} . Thus $|w| \geq 2^{n-1}$. $\square$

It turns out that the shortest word that reduces to ϵ accepted by the DFA M_n in the proof of Proposition 4 is related to the well-known ruler sequence, $(\nu_2(n))_{n \geq 1}$, where $\nu_2(n)$ denotes the exponent of the highest power of 2 dividing n . This sequence has many interesting characterizations including being the lexicographically least infinite squarefree word over $\mathbb{Z}$. For integers $k > 0$, let $r_k = (\nu_2(n))_{1 \leq n < 2^k}$ be the prefix of length $2^k - 1$ of the ruler sequence. For example, $r_3 = 0102010$.

Let w_n be the shortest word accepted by M_n that reduces to ϵ . Let w'_n be the prefix of w of length $|w| - 2$. This is well defined for $n \geq 3$. Also let $w_n = w'_n = \epsilon$ for $n = 2$. Then for any integer $n \geq 3$, we have $w_n = w'_{n-1}(n-2)w'_{n-1}(n-2)^{-1}1^{-1}1$. It can be easily verified that this word is accepted by M_n . Now define the homomorphism h such that $h(a) = a$ for $a \in \Gamma$, and $h(a) = \epsilon$ for $a \in \Gamma^{-1}$. Then $h(w_n) = r_{n-2}1$.

The next proposition shows that over a fixed alphabet size we can still get an exponential lower bound.

Proposition 5. *For each integer $n \geq 1$ there exists a DFA, M_n with $3n + 1$ states over the alphabet $\Sigma = \Gamma \cup \Gamma^{-1}$, where $\Gamma = \{1, 2\}$ and $\Gamma^{-1} = \{1^{-1}, 2^{-1}\}$, with the property that the only word $w \in L(M_n)$ such that $r(w) = \epsilon$ has length $|w| = 3 \cdot 2^n - 4$.*

Proof. The proof is constructive. Let M_n be the DFA $(Q, \Sigma, \delta, q_n, F)$ where $Q = \{q_{-1}, q_0, q_1, p_1\} \cup \{p_i, q_i, r_i : 2 \leq i \leq n\}$, $F = \{p_n\}$, and

$$\delta(q_a, c) = q_{a-1}, \text{ if } 1 \leq a \leq n, \text{ and either } c = 1 \text{ and } a \equiv 1 \pmod{2}, \\ \text{or } c = 2 \text{ and } a \equiv 0 \pmod{2}.$$

$$\delta(p_a, c) = \begin{cases} p_{a+1}, & \text{if } 1 \leq a \leq n-1, \text{ and either } c = 1 \text{ and } a \equiv 0 \pmod{2}, \\ & \text{or } c = 2 \text{ and } a \equiv 1 \pmod{2}, \\ r_{a+1}, & \text{if } 1 \leq a \leq n-1, \text{ and either } c = 1^{-1} \text{ and } a \equiv 0 \pmod{2}, \\ & \text{or } c = 2^{-1} \text{ and } a \equiv 1 \pmod{2}. \end{cases}$$

$$\delta(r_a, c) = q_{a-1}, \text{ if } 2 \leq a \leq n, \text{ and either } c = 1^{-1} \text{ and } a \equiv 1 \pmod{2}, \\ \text{or } c = 2^{-1} \text{ and } a \equiv 0 \pmod{2}.$$

$$\delta(q_0, a^{-1}) = p_1$$

Any other transitions lead to the dead state q_{-1} . The case $n = 4$ is illustrated in Figure 4.

Fig. 4. M_4 : a $3 \cdot 4 + 1$ state DFA with the property that the only reducible word accepted by it has length $3 \cdot 2^4 - 4$. (The dead state is not represented.)

In order to prove the statement, for each integer $m \geq 0$, let us consider the set C_m of pairs of states, others than the dead state, which are connected by a reducible word of length m , i.e.

$$C_m = \{(s', s'') \in Q' \times Q' : \exists w \in \Sigma^* \text{ s.t. } |w| = m, r(w) = \epsilon, \text{ and } \delta(s', w) = s''\},$$

where $Q' = Q \setminus \{q_{-1}\}$. We notice that $C_m = \emptyset$, for m odd. Furthermore $C_0 = \{(s, s) : s \in Q'\}$ and, for $m > 0$, $C_m = C'_m \cup C''_m$, where:

$$C'_m = \{(s', s'') : \exists (r', r'') \in C_{m-2}, a \in \Sigma \text{ s.t. } \delta(s', a) = r' \text{ and } \delta(r'', a^{-1}) = s''\}, \quad (1)$$

$$C''_m = \{(s', s'') : \exists m', m'' > 0, (s', r') \in C_{m'}, (r'', s'') \in C_{m''} \text{ s.t. } m' + m'' = m \text{ and } r' = r''\}. \quad (2)$$

We claim that, for each $m \geq 1$:

$$C_m = \begin{cases} \{(q_k, p_k)\}, & \text{if } \exists k, 1 \leq k \leq n, \text{ s.t. } m = 3 \cdot 2^k - 4; \\ \{(q_k, r_k), (r_k, p_k)\}, & \text{if } \exists k, 2 \leq k \leq n, \text{ s.t. } m = 3 \cdot 2^{k-1} - 2; \\ \emptyset, & \text{otherwise.} \end{cases} \quad (3)$$

We prove (3) by induction on m .

As already noticed, $C_1 = \emptyset$. By inspecting the transition function of M_n , we can observe that $C_2 = \{(q_1, p_1)\}$. Notice that $2 = 3 \cdot 2^1 - 4$. This proves the basis.

For the inductive step, we now consider $m > 2$ and we suppose (3) true for integers less than m .

First, we show that we can simplify the formula (2) for C_m'' . In fact, using the inductive hypothesis, for $0 < m', m'' < m$, the only possible $(s', r') \in C_{m'}$ and $(r'', s'') \in C_{m''}$ satisfying $r' = r''$ are the pairs $(q_j, r_j), (r_j, p_j) \in C_{3 \cdot 2^{j-1} - 2}$, obtained by taking $m' = m'' = 3 \cdot 2^{j-1} - 2$, for suitable values of j . This, together with the condition $m' + m'' = m$, restricts the set C_m'' to:

$$C_m'' = \{(s', s'') \mid \exists r \in Q : (s', r) \in C_{m/2} \text{ and } (r, s'') \in C_{m/2}\}. \quad (4)$$

Now we consider three subcases:

Case 1: $m = 3 \cdot 2^k - 4$, with $k \geq 2$.

An easy verification shows that $m - 2$ cannot be expressed in the form $3 \cdot 2^j - 4$ or in the form $3 \cdot 2^j - 2$, for any j . Hence, by the inductive hypothesis, $C_{m-2} = \emptyset$. By (1), this implies $C_m' = \emptyset$, and then $C_m = C_m''$.

We now compute C_m'' using (4) and the set $C_{m/2}$ obtained according to the inductive hypothesis. We observe that $m/2 = 3 \cdot 2^{k-1} - 2$. Hence, for $k \leq n$, $C_{m/2} = \{(q_k, r_k), (r_k, p_k)\}$ and, thus, $C_m = C_m'' = \{(q_k, p_k)\}$. On the other hand, if $k > n$ then $C_{m/2} = \emptyset$, which implies $C_m = C_m'' = \emptyset$.

Case 2: $m = 3 \cdot 2^{k-1} - 2$, with $k \geq 2$.

First, we observe that $m/2$ cannot be written either as $3 \cdot 2^j - 4$ or as $3 \cdot 2^j - 2$. Hence, by the inductive hypothesis, the set $C_{m/2}$ must be empty. Thus, $C_m = C_m'$.

We compute C_m' as in (1), using the set C_{m-2} obtained according to the induction hypothesis. We notice that $m - 2 = 3 \cdot 2^{k-1} - 4$. If $k > n + 1$ then $C_{m-2} = \emptyset$, thus implying $C_m = C_m' = \emptyset$. Otherwise, $C_{m-2} = \{(q_{k-1}, p_{k-1})\}$. In order to obtain all the elements of C_m' , we have to examine the transitions entering q_{k-1} or leaving p_{k-1} . For $k = n + 1$ there are no such transitions and, hence, $C_m = C_m' = \emptyset$. For $k \leq n$ all the transitions entering q_{k-1} or leaving p_{k-1} involve the same symbol $a \in \{1, 2\}$ or its inverse: there are exactly two transitions entering q_{k-1} ($\delta(q_k, a) = \delta(r_k, a^{-1}) = q_{k-1}$) and exactly two transitions leaving p_{k-1} ($\delta(p_{k-1}, a) = p_k$ and $\delta(p_{k-1}, a^{-1}) = r_k$). Hence, by the appropriate combinations of these transitions with the only pair (q_{k-1}, p_{k-1}) in C_{m-2} , we get that $C_m = C_m' = \{(q_k, r_k), (r_k, p_k)\}$.

Case 3: Remaining values of m .

If $m = 3 \cdot 2^{k-1}$ with $k \geq 2$, then $C_{m-2} = \{(q_k, r_k), (r_k, p_k)\}$. All the transitions entering or leaving r_k use the same symbol a^{-1} , with $a \in \{1, 2\}$, while all the transitions entering q_k or leaving p_k use the other symbol $b \in \{1, 2\}$, $b \neq a$, or b^{-1} . Hence, from (1), $C_m' = \emptyset$.

For all the other values of m , the form of $m - 2$ is neither $3 \cdot 2^j - 4$ nor $3 \cdot 2^j - 2$. This implies that $C_{m-2} = \emptyset$ and, then, C_m' must be empty. Hence, we conclude that $C_m = C_m''$.

Suppose $C_m'' \neq \emptyset$. From (4) and the inductive hypothesis, it follows that $m/2 = 3 \cdot 2^{j-1} - 2$ for some j , thus implying $m = 3 \cdot 2^j - 4$. This is a contradiction, because the values of m we are considering are not of this form. Hence, $C_m = C_m''$ must be empty.

This completes the proof of (3).

Recall that the initial state of M_n is q_n , while the only final state is p_n . Hence, the length of the shortest reducible word accepted by M_n is the smallest integer m such that $(q_n, p_n) \in C_m$. According to (3), we conclude that such a length is $3 \cdot 2^n - 4$.

From (3), it also follows that there are no reducible words accepted by M_n whose length is different than $3 \cdot 2^n - 4$. With some small refinements in the argument used to prove (3), we can show that M_n accepts exactly one reducible word. In particular, for $k \geq 1$ we consider:

$$w_k = \begin{cases} 11^{-1}, & \text{if } k = 1; \\ 1w_{k-1}1^{-1}1^{-1}w_{k-1}1, & \text{if } k > 1 \text{ and } k \text{ odd;} \\ 2w_{k-1}2^{-1}2^{-1}w_{k-1}2, & \text{otherwise.} \end{cases}$$

By an inductive argument it can be proved that w_k is the only reducible word such that $\delta(q_k, w_k) = p_k$ and $|w_k| = 3 \cdot 2^k - 4$. $\square$

We now examine the special case where $\Sigma = \{1, 1^{-1}\}$, and give a cubic upper bound and quadratic lower bound. The next proposition gives the upper bound, which holds even in the nondeterministic case.

Proposition 6. *Let $M = (Q, \{1, 1^{-1}\}, \delta, q_0, F)$ be an NFA with n states such that $\epsilon \in r(L(M))$. Then M accepts a reducible word of length at most $n(2n^2 + 1)$.*

Proof. We prove the result by contradiction. Assume the shortest $w \in L(M)$ such that $r(w) = \epsilon$ has $|w| > n(2n^2 + 1)$. Define a function b on words by $b(z) = |z|_1 - |z|_{1^{-1}}$ for $z \in \Sigma^*$. Roughly speaking, the function b measures the “balance” between the number of occurrences of the symbol 1 and those of the symbol 1^{-1} in a word.

Suppose that no factor w' of w has $|b(w')| > n^2$. Then the function b can take on at most $2n^2 + 1$ distinct values. Since $|w| > n(2n^2 + 1)$, there must be a value C such that b takes the value C for more than n different prefixes of w . That is, there is some $\ell \geq n$ such that $w = xy_1y_2 \cdots y_\ell z$ where the y_i are nonempty and

$$b(x) = b(xy_1) = b(xy_1y_2) = \cdots = b(xy_1y_2 \cdots y_\ell).$$

Consider a sequence of $\ell + 1$ states $p_0, p_1, \dots, p_\ell \in Q$, and a state $q_f \in F$, such that during an accepting computation M makes the following transitions:

$$p_0 \in \delta(q_0, x), p_1 \in \delta(p_0, y_1), \dots, p_\ell \in \delta(p_{\ell-1}, y_\ell), q_f \in \delta(p_\ell, z)$$

Since $\ell \geq n$, a state must repeat in the above sequence, say $p_i = p_j$ with $i < j$. Then $u = xy_1 \cdots y_i y_{j+1} \cdots y_\ell z$ is shorter than w (since we have omitted

$y_{i+1} \cdots y_j$) and it is accepted by M . Furthermore, observing that $b(y_{i+1} \cdots y_j) = 0$, we conclude that $r(u) = \epsilon$. Since $|u| < |w|$, this is a contradiction to our choice of w . Hence, w must contain a factor w' of w such that $|b(w')| > n^2$.

Let y be the shortest factor of w such that $b(y) = 0$ and $|b(y')| > n^2$ for some prefix y' of y . We can write $w = xyz$, for suitable words x, z . Let D be the maximum value of $|b(y')|$ over all prefixes y' of y . We suppose that $D > 0$. (The argument can be easily adapted to the case $D < 0$.) For $i = 0, 1, 2, \dots, D$, let $R(i)$ be the shortest prefix of y with $b(R(i)) = i$. Similarly, let $S(i)$ be the longest prefix of y with $b(S(i)) = i$. Again, consider an accepting computation of M on input w . For each pair $[R(i), S(i)]$, let $[P(i), Q(i)]$ be the pair of states such that M is in state $P(i)$ after reading $xR(i)$ and M is in state $Q(i)$ after reading $XS(i)$. Since $D > n^2$, some pair of states repeats in the sequence $\{[P(i), Q(i)]\}$. That is, there exists $j < k$ such that $[P(j), Q(j)] = [P(k), Q(k)]$. We may therefore omit the portion of the computation that occurs between the end of $R(j)$ and the end of $R(k)$ as well as that which occurs between the end of $S(k)$ and the end of $S(j)$ to obtain a computation accepting a shorter word u such that $r(u) = \epsilon$. Again we have a contradiction, and our result follows. $\square$

The following proposition gives a quadratic lower bound.

Proposition 7. *For each integer $n \geq 0$ there exists a DFA M_n with $n+1$ states, over the alphabet $\Sigma = \{1, 1^{-1}\}$, such that the only reducible word $w \in L(M_n)$, has length $(n+1)(n-1)/2$ if n is odd, and $n^2/2$ if n is even.*

Proof. The proof is constructive. Let M_n be the DFA $(Q, \Sigma, \delta, q_0, F)$, illustrated in Figure 5, where $Q = \{q_{-1}\} \cup \{q_i : 0 \leq i < n\}$, $F = \{q_{\lfloor \frac{n}{2} \rfloor}\}$, and

$$\delta(q_a, c) = \begin{cases} q_{a+1}, & \text{if either } c = 1 \text{ and } 0 \leq a < \lfloor \frac{n}{2} \rfloor, \\ & \text{or } c = 1^{-1} \text{ and } \lfloor \frac{n}{2} \rfloor \leq a \leq n-2; \\ q_{a \bmod 2}, & \text{if } c = 1^{-1} \text{ and } a = n-1. \end{cases}$$

Any other transitions lead to the dead state, q_{-1} .

Observe that if n is odd, then each word w accepted by M_n has the form $w = (1^{\frac{n-1}{2}} 1^{-\frac{n+1}{2}})^\alpha 1^{\frac{n-1}{2}}$, for an $\alpha \geq 0$. Computing the “balance” function b introduced in the proof of Proposition 6, we get $b(w) = \frac{1}{2}(n-1-2\alpha)$, which is 0 if and only if $\alpha = \frac{n-1}{2}$. Finally, by computing the length of w for such an α , we obtain $(n+1)(n-1)/2$.

Similarly, in the case of n even, we can prove that the only reducible word accepted by M_n has length $n^2/2$. $\square$

Fig. 5. Top: M_n where n is odd. Bottom: M_n where n is even.

5 Counterexamples

Here we look at counterexamples that solve two natural questions. The first question is whether the set of all equivalent words to those in a regular language must be regular. The second question is whether any of our results hold for a more generalized form of the reduced representation. We now define the set of equivalent words.

Definition 2. For $w \in \Sigma^*$, the set of equivalent words is

$$\text{eq}(w) = \{w' : r(w) = r(w')\}$$

For $L \subseteq \Sigma^*$, the set of equivalent words is

$$\text{eq}(L) = \{\text{eq}(w) : w \in L\}$$

Proposition 8. There exists $L \subseteq \Sigma^*$ such that L is regular but $\text{eq}(L)$ is not.

Proof. Consider the following example. Let $\Sigma = \{1, 1^{-1}\}$ and let $L = \{\epsilon\}$. Then $\text{eq}(L)$ is the language of balanced parentheses, which is well known to be nonregular. $\square$

Proposition 9. Let L be a regular language over an alphabet Σ . The language $\text{eq}(L)$ is context-free.

Proof. Let M be a DFA accepting L . We first construct the ϵ -NFA M_r of Proposition 1 that accepts $r(L)$. We then reverse the transitions of M_r to obtain an ϵ -NFA A that accepts the reversal of $r(L)$. We now construct a PDA B that accepts $\text{eq}(L)$. The operation of B is as follows. On input w , the PDA B reads each symbol of w and compares it with the symbol on top of the stack. If the symbol being read is a and the symbol on top of the stack is the inverse of a , the

machine B pops the top symbol of the stack. Otherwise, the machine B pushes a on top of the stack. After the input w is consumed, the stack contains a word z that is equivalent to w . Moreover, since z does not contain any factor of the form aa^{-1} , the word z must equal $r(w)$ by Lemma 1. Finally, on ϵ -transitions, the PDA B pops each symbol of z off the stack and simulates the computation of A on each popped symbol. The net effect is to simulate A on z^R (the reversal of z). If z^R is accepted by A , the PDA B accepts w . Since z^R is accepted by A if and only if $z \in r(L)$, the PDA B accepts w if and only if $r(w) \in r(L)$. However, we have $r(w) \in r(L)$ if and only if $w \in \text{eq}(L)$, so B accepts $\text{eq}(L)$, as required. $\square$

A set of equivalent words as described above can be thought of as an equivalence class under an equivalence relation described by a very particular set of equations: for all $a \in \Sigma$, $aa^{-1} = \epsilon$. Our generalization is to allow for an arbitrary set of equations, which we will refer to as the “defining set of equations”. Then a generalized reduced representation of a word is an equivalent word such that there are no shorter equivalent words. It is no longer necessary that reduced representation be unique, so we denote the set of generalized reduced representations of a word w as $r_g(w)$. For example, if $\Sigma = \{a, b, c, d\}$ we may have the defining set of equations $\{ab = cd, bc = a\}$. Then $\text{eq}(abd) = \{abd, cdd, bcbd\}$ and $r_g(aabd) = \{abd, cdd\}$. It is natural to wonder whether an analogous result to Corollary 1 holds under this generalized form of reduced representations.

Proposition 10. *There exists $L \subseteq \Sigma^*$ such that L is regular but $r_g(L)$ is not even context-free.*

Proof. Consider the following example. Let $\Sigma = \{a, b, c\}$, let the defining set of equations be $\{ab = ba, ac = ca, bc = cb\}$ and let $L = (abc)^*$. Then $r_g(L)$ is the language $\{x : |x|_a = |x|_b = |x|_c\}$, which is known to be noncontext-free, and hence also nonregular. $\square$
